## Introduction

The historic masculinization of the population at birth and initial ages in the country continues in spite of several initiatives from the government of India to balance the female-male populations. It has been more than two decades since the inception of the Pre-Conception and Pre-Natal Diagnostic Techniques (Prohibition of Sex Selection) Act (PC-PNDT Act), but the impact of the initiative is limited as the problem of sex-selective abortions continue to persist (Sen, 2003; Jha et al., 2011; Myers, 2012; Arokiasamy and Goli, 2012; Stallard, 2016). The reports and the factsheet based on the National Family Health Survey (NFHS) IV (IIPS and MoHFW, 2017) and a few studies using this information (Radkar, 2018) from the factsheets present socio-economic and geographical pattern of Sex Ratio at Birth (SRB) in India but they hide much more than they reveal and to the extent misreport the estimates. Unlike the NFHS (2015-16) factsheets, findings based on Sample Registration System (SRS) data do not support the logic of disappearance of excess female child mortality. Therefore, the release of unit level information has facilitated us to re-examine the estimate of the NFHS IV factsheets and studies based on them. The NFHS factsheets show that the Child Sex Ratio (CSR) has been improved and the SRB is worsening (IIPS and MoHFW, 2017), which indicate a disappearance of excess female child mortality in India which is impossible by any logic and thus not true. This ambiguity shows that there is a need to recheck the estimates presented in the NFHS IV factsheets by re-estimating it from the unit level data. At an outset, we have threefold objectives for this study. First, to re-estimate SRB and CSR by socio-economic groups, states, and districts using unit level information of NFHS IV (2015-16). Second, is to present the trends in SRB and CSR with a uniform definition by states and socio-economic groups since 1990s using
successive rounds of NFHS. Third, is to estimate the recent correlates of skewed CSR, SRB, and SRLB in India.

## Background

In most societies in the world, culturally females have always a lower perceived value than males. Historically lower perceived utility of girls over boys continuously making girls marginalized in terms of their numbers in the population. In 1662, John Graunt was the first to observe the difference between the number of males and females at birth, which set a curiosity among researchers to look into this disparity in the number of males and females in a population (Chahnazarian, 1990; Campbell, 2001). In India, this deficit of females had been evident from the very first Indian decennial Census in 1872 (Visaria, 2005). The overall sex ratio (female per thousand males) has declined from 972 (1901) to 940 (2011) in 110 years (Appendix Table 1). In late 1990s Amartya Sen came with the magnitude of the masculinization and analyzed the number of "missing girls" from the population of Asia. After that many demographers estimated the missing girls from Indian population (George, 2006, Kulkarni, 2007; Sahni et al., 2008; Gupta et al., 2009; Jha et al., 2011). A Growing number of studies also report a continuous decline in the sex ratio in initial ages (0-6) (see appendix table 2) and at birth (Kundu and Sahu, 1991; Rajan et al., 1991; Raju and Premi, 1992; Nair, 1996; Premi, 2001; Agnihotri, 2000, 2003; Guilmoto and Depledge, 2008; Arokiaswamy and Goli, 2012). Moreover, this ascendancy of the number of males in population exists in every stage of life cycle except in older population, because of different type of neglect in terms of health, nutrition, hygiene and financial resources faced by females at the time of birth, childhood, adolescence, marriage, pregnancy, and illness. The previous studies attribute the India's distorted child sex ratios to the factors like, sex-selective abortions, female infanticide and foeticides and excess female child mortality and also due to under-enumeration of female population (Das Gupta 1987; Kishore 1993; Sen 1992; Bhat, 2002; Arnold, Kishor and Roy, 2002; Bhat and Zavier, 2007; Arokiaswamy, 2004; Visaria, 2005; Malhotra and Kant, 2006; Bongaarts and Guilmoto, 2015). The economic survey of 2018 come up with the concept of "son meta preference" which depicts the level of son preference in the society and how the couples are stopping their fertility after achieving the desired number of the son in their family.

## Context and Rationale

Although, previous studies have already revealed the possible reasons of skewed sex ratio at birth and early ages, the analyses using the most recent NFHS data released in January 2018 will make us cognizant of the recent positive or negative change in SRB and CSR across different geographical and socio-economic settings. This study is meant to document the most recent socioeconomic and geographic trend and patterns considering uniform definition across the successive rounds of NFHS. This study tests how far "north-west and south-east" divide, "Bermuda triangle" and "rice and wheat belt" hypotheses previously used to explain the geographical pattern of sex ratio (Miller 1981, Kishor, 1993; Raju, 1997; Agnihotri, 1994), are still valid in the present context. For the first time, NFHS allow us to estimate district level SRB and Sex Ratio at Last Birth (SRLB) which helps to test above said hypotheses with robust measures. This study also tries to bring out the driving factors of SRB, CSR, and SRLB in the context of socio-economic settings in the country. The economic Survey (2018) has taken note of the behavioural pattern of Indian parents who prefer to have children "until the desired number of sons is born" and termed it as "Meta Son Preference" (Government of India, 2018), but hardly there is any study which comprehensively documented the impact of stopping rule behaviour ${ }^{1}$ on SRLB.

## Data

This study used the census data for analyzing the long-term trends (1961 to 2011) in overall sex ratio and sex ratio of children in 0-6 year age group. The NFHS data (1992-93, 1998-99, 2005-06 and 2015-16) has been used to analyze the emerging geographical and socio-economic pattern of CSR, SRB, and SRLB. The appropriate weight has been used to make the estimates representative and to account for multistage sampling design. The NFHS IV (2015-16) data is being analyzed to see the socio-economic correlates of CSR, SRB, and SRLB.

## Methods

The methodology in this paper involves calculation of CSR from census by using sex-wise population in 0-6 year age group. The direct estimation of CSR, SRB and the SRLB was carried out using unit level information from the successive round of NFHS. The CSR is estimated as female/male ratio of living child population of 0 to 72 months, while the SRB and SRLB were calculated as female/male ratio of total births in the five complete calendar years:1987-1991 (NFHS I), 1993-1997 (NFHS II), 2000-2004 (NFHS III) and 2010-2014 (NFHS IV). Further the geographical pattern of CSR, SRB, and SRLB is represented through Arc GIS.

For validation of our estimates, we compare it with SRBs from SRS data. Figure 1 shows a correlation between the estimated SRBs based on NFHS (2015-16) and SRS (2013-15). The correlation (r) is as high as 0.80 , which shows there is not much deviation of our estimated from SRS estimates.

Figure 1 Correlation between the estimates of SRB from SRS (2013-15) and NFHS (2015-16)

Binary logistic regression is used to find out the drivers of skewed sex ratio in child population, at birth, and at last birth. In this model, the dependent variables are the number of males compare to females in 0-6 year age group and number of males compared to females at birth and last birth. All the background characteristics (sex preference, social groups, religion, educational status,
wealth quintile, place of residence and region) are independent variables. The mathematical expressions of the models are given elsewhere (see Retherford and Choe, 1991)

We used human fertility decision model to assess the effect of stopping rule behaviour on SRLB which stimulate that couple's parity progression continues until they achieve the desired sex composition.

Assumptions made here are as follows:

If the woman has the child at parity i

1. The probability of having a boy $=p$
2. The probability of having a girl $=1-\mathrm{p}$

If the sex ratio is 105 (biological or normal sex ratio)
3. Then $p=0.512$
4. $1-\mathrm{p}=0.488$
5. The probability of having all girls at parity $\mathrm{I}=(1-\mathrm{p}) \mathrm{i}$.

If women move to next parity $\mathrm{i}+1$
6. Probability of having all girls at parity $i+1=(1-p) i+1$. *the probability of having all girls will decline and having all boys will have increased by moving to next parity $\mathrm{i}+1$.

## Findings

## Trends in sex preference, CSR, SRB, and SRLB

The estimates based on the four rounds of NFHS found that the sex ratio of the child population is continuously masculinizing (Table 1). There was strong son preference ${ }^{2}$ in 1992-93 but over the period it is decreasing, and by 2015-16 it is decreased by half to the level of 1992-93 (46.25 \% in 1992-93 to $26.43 \%$ in 2015-16). Nevertheless, the CSR, SRB, and SRLB have not shown a remarkable improvement. The proportion of women preferring for a girl child is very less during the entire period, as it was only $2.86 \%$ in 1992-93 and 3.63 in 2015-16. SRB shows a declining trend from 1992-93 to the 2015-16. The SRLB is adverse compared to all the other indicators of sex ratio. It was 873 in 1992-93 which declined to 803 girls in 2015-16. The decline in CSR (0-6
year age group) is also at the alarming stage. The number of girls per thousand boys in the $0-6$ year age group is decreased to 916 in 2015-16 from 944 in 1992-93.

Note: SRB is calculated for children born five complete calendar years taken from birth history data of all the four rounds of NFHS.

## The socio-economic pattern of CSR

Sex ratio among the child population (0-6) is considerably varied by socio-economic background characteristics (Table 2). Among women with son preference, the CSR is as low as 776 females per thousand males in 2015-16 compared to those with no son preference (941). In India, socioeconomic background characteristics of women have been showing a strong influence on many demographic indicators. Our estimates of CSR by social groups shows that initially Scheduled Castes (SCs) has the lower sex ratio (895) than all other social groups in 1992-93 but the situation has changed in last 20 years; the SCs are doing better in terms of CSR while other social groups are getting worse. Scheduled Tribes (STs) are also exposed to the culture of eliminating female child or limiting the family size after attainment of the required number of sons which indirectly restrain the female birth in the presence of sex-selective abortions. Muslims (956) and Christian (978) had the better CSR in 1992-93, and they are continued to be on top in 2015-16 with 965 and 1067 girls in 0-6 year age group. Sikhs had the lowest number of girls in child population with CSR of 878 in 1992-93 and declined to 807 in 1998-99. In 2015-16, NFHS IV data captures an improvement in CSR, although this improvement is appreciable still there is a long way to reach biological normal sex ratios as it currently stands at 872 (2015-16) girls per thousand boys in 0-6 year age group.

Table 2 also shows that women with no education have the lowest CSR (929) in 1992-93 but improved to highest (949) in 2015-16. In 2015-16, the results suggest that lower the educational level better is the CSR. This pattern can be attributed to their high fertility or non-exposure to the sex determination techniques among women with no or lesser education in comparison to their higher educated counterparts. A general notion of "Higher the wealth, better the women's position" seems to be a myth. From 1992-93 (1057) to 2015-16 (951) the poorest population have better child sex ratio than richer or richest households. Initially, the urban and rural settings have the same CSR (945 each in 1992-93), but in 2015-16 the CSR has declined more in urban India and currently stands at 899 girls per thousand boys in 0-6 year age group whereas the their rural counterparts have 924 girls per thousand boys.

## The socio-economic pattern of SRB

The SRB is also worsening (794 in 1992-93 to 756 in 2015-16) over the period among the women with son preference (Table 3). Except for SCs the number of girls born per thousand boys has been worsening in all social groups from 1992-93 to 2015-16. Even among the STs, who believed to be having better SRBs in the past, shown a decreasing trend (973 in 1992-93 to 953 in 2015-16). Among all the religions, Sikhs are eliminating larger number of girls at birth and in early childhood. The SRB among Sikhs is getting slightly better from its previous values of 835 in 1992-93 to 861 in 2015-16, although such smaller improvement in a 20 years span could not help in balancing the SRB. Christian shows better SRB in comparison to other religion in India (1017 in 1992-93 and 956 in 2015-16).

In 1992-93 the SRB was found to be better among primary (968) and secondary educated women (965) in comparison to the highly educated women (934), but in 2015-16 it gets adversely worse among the former than the later educational group. The SRB is found to be lowest among the women with secondary level of education in 2015-16. The households with the poorest income quintile have the highest number of girls (1031) born per thousand boys born in 1992-93, but it reduced to 939 in 2015-16. Among all the income groups the middle (892) and richest (845) households have the lowest SRB in 2015-16. Both rural and urban India is continuously evident for missing girls at birth from last two decades (Table 3). But comparatively urban India (895) has significantly less number of girls born to every thousand boys than rural India (917) according to 2015-16 estimates.

Note: SRB is calculated for all births in the five complete calendar years (1987-1991, 1993-1997, 2000-2004 and 2010-2014) taken from birth history data of all round of NFHS 1, NFHS 2, NFHS 3 and NFHS 4.
*Wealth Index for NFHS 1 (1992-93) and NFHS 2 (1998-99) are calculated by authors.

## The socio-economic pattern of SRLB

Among women with son preference the SRLB is as low as 638 girls per one thousand boys in 2015-16 (see Table 4). Among social groups, the SRLB is lowest in SCs (866) in 1992-93, but in 2015-16 it observed to be lowest in OBC (786) and other castes (779). Hindus and Sikhs have the lowest SRLB in 1992-93, and it is continuing to be at the worse position after two decades, as it reduced to 793 and 663 for Hindu and Sikhs in 2015-16 respectively. In 1992-93 among all the educational groups the primary educated women have better SRLB in comparison to highly educated women, but from 1998-99 in all educational categories, the figures of SRLB are declining among women with different educational attainment whereas it has shown some improvement among women with higher education. The SRLB was better among poorest (950) in 1992-93 but it started worsening and it reached to 821 girls per thousand boys in 2015-16. In 2015-16, the SRLB is found to be lower among poor (866) and richest (899) population, while SRLB in richest (765) population is lowest. In contrast to CSR and SRB pattern, the SRLB is worse in rural India (791) compared to urban (814) in 2015-16. Lower SRLB and higher CSR and SRB in rural areas suggest that they have been benefiting from higher fertility rates compared to urban areas.

## The geographical pattern of CSR, SRB, and SRLB

The disparity in terms of sex ratio among Indian states is not a new phenomenon, and this regional inconsistency is revealed by time to time from different data sources like the census, vital statistics and sample surveys (Ramchandran and Deshpande, 1964; Agnihotri, 2000; Guilmoto and Depledge, 2008; Arokiasamy, 2004; Kumar and Sathyanarayana, 2012). As per the sex ratio scenario, a north-south divide has been noticed which is also described as rice and wheat belt divide where rice belt includes all the southern and eastern parts of the country and the wheat producing areas are mainly concentrated in western parts (Miller 1981, Kishor, 1993; Raju, 1997). Agnihotri in 1996 found that the dearth of females in the primary age group is prevalent in north and north-west part of India and termed this region as "Bermuda triangle" which includes districts of Haryana, ravine area of Madhya Pradesh, Rajasthan and western Uttar Pradesh. Here, in this paper, the analysis of recent data shows an emerging geographical pattern of sex ratio in the 0-6 year age group and at birth. Although, the most recent census (2011) continue to support the fact that the north, west, and central India is mainly contributing to the decline in the CSRs at the national level, but also hints the decline the CSR in several districts of south and eastern India (Arokiasamy and Goli, 2012). Now it's been seven years after the last census conducted, the analyses based on 2015-16 data shows an emerging pattern in CSR and SRB (see table 5, 6 and table 7).

Table 5 shows that the south Indian states like Tamil Nadu (1051), Andhra Pradesh (1006), Kerala (969) and Karnataka (949) have higher CSR than many north Indian states in the year 1992-93. In states like Andhra Pradesh and Tamil Nadu, female outnumbered the male in
child (0-6) population in 1992-93. However, over the period during 1992-93 to 2015-16, the CSR deteriorated in every south Indian state except Kerala (1025). Despite being one of the southern and rice cultivating Indian states, Telangana (912) has very less number of girls than boys in 0-6 year age group in 2015-16. In 1992-93, the northern states, Delhi (904), Punjab (887), Rajasthan (877) and Haryana (859) have the least number of girls in child population, and these states are continuing to be at the bottom till 2015-16. In 2015-16, the north-eastern states like Manipur (982), Meghalaya (1014), Mizoram (946) and Nagaland (949) have better sex ratios in comparison to many north Indian states like Delhi (835), Uttar Pradesh (904), Bihar (935) and Jammu \& Kashmir (911). Overall, a majority of the Indian states have experiencing a declining trend in the number of girls per thousand boys in the child population. From 1992-92 to 2015-16, the states which have shown an improvement in child CSR are Kerala (+56), Himachal Pradesh (+44), Meghalaya (+40), Arunachal Pradesh (+30), Mizoram (+13), Rajasthan (+6) and Odisha (+1). Although, it was widely discussed and documented about north-south or east-west divide in CSR patterns by the previous studies, our trend analysis suggest that CSR is undoubtedly declining in almost all part of India and leading to an emerging geographical patterns of sex ratio imbalance in the country.

Table 5: Child Sex Ratios for all States of India, 1992-93 to 2015-16

SRB is getting deteriorated in almost all the states of India (Table 6). The southern India, which is known for its better demographic indicators have also not remained untouched by this demographic constraint. From 1992-93 to 2015-16 the states which have shown an improvement in SRB are Himachal Pradesh (+78), Kerala (+38), Jammu \& Kashmir (+30), Punjab (+17), Mizoram (+6) and Nagaland (+12), except these states all other have declining trend from last two decades. The newly formed Telangana also have very less number of girls (875) per thousand boys at birth. In 2015-16, among major Indian states, Haryana (846) and Punjab (845) are continuously displaying lowest SRB. Since 1992-93 the north-eastern states like Mizoram (+6), Tripura (+28) Nagaland (+12) have shown positive growth in the number of girls at birth. But the remaining states like Meghalaya and Manipur have very less number of girls per thousand boys at birth from last two decades. Top five states where the SRB is better in 2015-16 are, Kerala (1028), Meghalaya (992), Mizoram (986), Manipur (964) and

Chhattisgarh (958) and the bottom five states where the SRB is worst in 2015-16 are Sikkim (802), Delhi (820), Punjab (845), Haryana (846) and Rajasthan (869).

Table 7 shows the trend of SRLB in all Indian states from 1992-93 to 2015-16. The top states where the SRLB is comparatively better in 2015-16 are Kerala (921), Meghalaya (918), Mizoram (916), Tamil Nadu (927), and Manipur (915) and the states at the bottom are Gujarat (660), Delhi (671), Punjab (674), Rajasthan (675) and Haryana (697). The northern states like, Himachal Pradesh (709), Uttarakhand (755) and Uttar Pradesh (755) have less number of girls at last birth in 2015-16 in comparison to many south Indian and north-eastern states. The SRLB is very low in almost all parts of the country. From 1992-93 to 2015-16, the state which has added more girls at last birth from earlier are Goa (+15) Karnataka (+20) Kerala (+38) Mizoram (+33) and Nagaland (+3), except these five states all the remaining states have less number of girls at last birth in 2015-16 in comparison to 1992-93. The sex ratio at last birth shows the level of son preference and stopping rule behaviour of couples, as the people stopping childbearing once they achieved a desired number of son.

Table 7: Sex Ratio at Last Birth for all states of India, 1992-93 to 2015-16

| States | 1992-93 |  |  | 1998-99 |  |  | 2005-06 |  |  | 2015-16 |  |  |

| Telangana | - | - | - | - | - | - | - | - | - | 868 | 835 | 903 |

Note: SRLB is calculated for all last births in the five complete calendar years (1987-1991, 1993-1997, 2000-2004 and 2010-2014) taken from birth history data of all round of NFHS 1, NFHS 2, NFHS 3 and NFHS 4.

As mentioned above for the first time the design and sample size in the NFHS IV allows for estimating CSR, SRB and SRLB at district levels. District level assessment allows better regionalisation of sex ratio imbalance in the country. Also, helps to evaluate the regionalisation proposed in the previous studies. The estimates of CSR over districts show a huge variation not only across the country but within states across the districts. The states like Kerala, Meghalaya, Maharashtra, and Chhattisgarh which has comparatively better CSR figures in terms of state averages also have districts with low CSR. Most of the districts with better CSR are clustered in the southern part of the country. Map 1 is clearly showing that the districts with better CSR in any state is clustered together, while the districts with worse CSR are also sharing the geographical boundaries. Across many districts of north India, the range of CSR varies between 500-900 girls per thousand boys. The whole eastern tribal belt of Madhya Pradesh, Odisha, Chhattisgarh and north-eastern states has better CSR levels. In contrast, most of the western districts have less than 900 girls per thousand boys. In many districts of India, there are less than 800 girls per thousand boys in the $0-6$ year age group. The north-eastern districts are better than western districts in terms of CSR. In Haryana, most of the districts have less than 800 girls per thousand boys in the $0-6$ year age group.

Akin to the pattern of CSR across the districts, the states having better SRB also have some parts (districts) with worse sex ratio. Thus, the map 2 shows that there is not only interstate diversity but also intrastate diversity in SRB. Although, the SRB levels are better in southern region, but there is also an emerging masculinisation process across the several districts in the region. In western India, except for few districts, most of the districts have worse SRB. The districts of east-central India also have better SRB than western India. Most of the districts of Jammu \& Kashmir and Himachal Pradesh have less than 900 girls per thousand boys at birth.

Map 2: District Pattern of Sex Ratio at Birth in India, 2015-16

As said previously, SRLB do not have any role in determining the overall sex ratio of the population in absence of sex-selective abortions, but it depicts the level of son preference existing in the society. Map 3 shows north and north western India display high meta son preference. The SRLB in western and northern India are lying between 400 to 800 girls per thousand birth. Although, southern India has more districts with better SRLB, but also have a cluster of districts with male skewed SRLB. In the north-east, we found there are only few districts with balanced SRLB. At an outset, the SRLB is overall skewed in every part of India except few geographical pockets of south and north-east.

Map 3: District Pattern of Sex Ratio at Last Birth in India, 2015-16

## Socio-economic factors of CSR, SRB and SRLB

Table 8 shows the effect of socio-economic factors on CSR, SRB, and SRLB. Model 1 represents the likelihood of having males than females in the 0-6 year age group. Results in model 1 have clearly shown that among women with son preference there is the high probability of having males than females after adjusting to all other socio-economic variables. Among social groups, the likelihood of having more male than female in 0-6 year age group is less in all other groups (SC, OBC and Others) in comparison to STs. The likelihood of having more male child among women with the primary and secondary level of education is higher than the women with no education. The probability of having males in 0-6 age is higher in the middle, rich and richest population than the poor population. North India shows the high probability of having more male child in comparison to the rest of India.

Model II presents the likelihood of having males than female at birth. The results of model II depicts that there is the higher likelihood of having males than females at birth in the presence of son preference. SCs and OBCs have less probability of having the son in comparison to STs. The probability of having more sons is high among the women with the primary and secondary level of education. The probability of having the more male child is highest among the richest women. Model III represents the likelihood of having more males than females at last birth. It is clearly shown in the result that there is the higher likelihood of having male at last birth if the last two births were female. In presence of son preference, there is the high probability of having males at last birth. Among all religion, Sikhs are more likely to have more male child at last birth. All the economic classes are more likely to have male child at last birth in comparison to poor class. The probability of having males at last birth is higher in urban areas than rural areas.

Table 8: Results from logistic regression models: Socio-economic Correlates of Child Sex Ratio (0-6 years), Sex Ratio at Birth and Sex ratio at Last Birth.

Note: * SRLB when the differential in stopping rule behaviour and termination of pregnancy not present or when assumed normal SRB 1050
** SRLB when the differential in stopping rule behaviour and termination of pregnancy present or actual SRB

The impact of stopping rule behaviour on SRLB is assayed through human fertility model. As parents wish to have at least one boy and keep having children until they attain their wish and often stop childbearing with the attainment of the son (Keyfitz and Caswell, 2005). The SRLB is a mirror of the level of son preference in a population. The SRLB may not affect the overall sex ratio, but it can't be sidelined during the study of sex ratio especially in the background of son preference. Here in table 9, it is shown that how the SRLB is being affected by the stopping rule behaviour and termination of the pregnancy. The result shows that where there is no stopping rule behaviour, the sex ratio is ranging from 730 to 1000 over different parities. But in presence of termination of pregnancy and the stopping rule behaviour the sex ratio is highly in favour of male and it is varying between 510 girls to 680 girls per thousand boys. In the absence of differential in stopping rule behaviour and termination of pregnancy the women with parity 1 have 950 girls per thousand boys at last birth but in the presence of both there are only 510 girls per thousand boys at last birth. Same has happened in women with higher parity, i.e., in the presence of termination of pregnancy and differential in stopping rule behaviour, the women bearing very few girls at last birth in comparison to its absence.

## Discussion and Conclusion

Beside PC-PNDT act, recently India has initiated new programmes for combating the issues related to gender imbalance out of which one key programme is "Beti Bachao, Beti Padhao" (BBBP). Although, the NFHS IV data will not allow the evaluation of the impact of BBBP as the launching of survey and BBBP programme is at the same time, but allows prioritizing the key challenges in front of fulfilling BBBP targets and allows for identifying the changing
"hot spots" of the problem by analyzing the trends and patterns of the sex ratio imbalance and key factors associated with it. This study based on 2015-16 data is showing the most recent trends of masculinisation of the population by estimating the SRB, CSR, and SRLB. Given that NFHS IV factsheets wrongly representing the trends in SRB and CSR, the study for the first time present the correct estimates of SRB and CSR since the release of NFHS IV factsheets and the data. A high correlation between the NFHS and SRS based estimates intersperse faith in our estimates.

The estimation from all the rounds of NFHS data shows that there is a declining trend in CSR, SRB, and SRLB against what has been reported in the factsheets of NFHS. A more surprising fact is in spite of decline in son preference almost by half, the masculinisation of the population at early ages continues. Over the period, except slight improvement of CSR in SCs and SRB in STs, in general CSR, SRB, and SRLB worsened across all the social groups. Masculinisation continues across the population in all the religious groups, educational level, and wealth quintiles. In spite of a slight improvement in SRB and SRLB among all the religious groups, Sikhs stands at the bottom in all three indicators CSR, SRB, and SRLB. The decline is significant among females with higher education, rich wealth quintile and urban residents than their counterparts. Meta son preference is a significant factor for highly skewed SRLB. Sex of the previous births is also a critical determinant of the sex of the subsequent child. Although, states from the north and north-west India continue to show a greater masculinization of the child population, the district level assessment shows assimilation of the culture of elimination of girl child in several districts of east and south India. Therefore, the previous notion of "rice" and "wheat" belt divide or "north-west" and "south-east" divide in sex ratio imbalance (Miller, 1981; Dyson and Moore, 1983) can’t be strictly valid now as the intra-regional variation are a new emerging pattern in all three indicators of sex ratios. The culture of elimination of girl child is spreading to southern, eastern and remote areas of central India with development of increasing communication and technological access.

In a policy perspective, we put forward that the act like PC-PNDT and recent initiatives such as BBBP and other conditional cash transfers which are mainly targeting the legal surveillance of births, behaviour and attitude changes and state-specific conditional cash transfers which needs to be strictly evaluated for their impact. We especially recommend not to target only below poverty line families or marginalized communities in these programmes because the problem of skewed CSR is in the wealthiest, urban and educated families as well.

We have also doubt, how much the awareness programmes mostly driven by advertisements work as the problem lies with most educated, wealthiest and urban communities who are well aware of the legal consequences of the elimination of the girl child. The state-specific trends suggest that a strict implementation and monitoring of PC-PNDT act is having some impact regarding improving the scenario of the sex ratio in highly focused states like Punjab, Haryana, and Rajasthan where the problem continues to be severe. The problem of sex ratio imbalance roots in patriarchy and overvaluing the sons over daughters. One-side we are promoting girl child education through the programme like BBBP, but on the other side, we are reducing spending on public education and health programmes (Ministry of Finance, 2018). The catastrophic expenditures in education, health and marriages are key factors which are more affecting the girls than boys and undermine the value of daughters in the society. By providing good education, better health care and employment opportunities which will improve the value of daughters and parents trust on daughters for old age security. The continuous religious divide in the sex ratio imbalance shows that interventions in religious culture and norms are must for improving the value of daughters in the society. There is must be a change in the norm of "raising daughters is like a watering neighbour's garden". As long as patrilineal and patrilocal societies continue, the parent's insecurity of lineage and old age social security continues which will keep on undermining the value of daughters. Unless, we raise the value of daughter in the Indian society and its culture, the problem can't be eliminated through legal measures or advertisements.

Source: Calculated by using 0-6 population in single year age group by sex from Socio- economic tables (1961-1981). Office of the Registrar General and Census Commissioner, India.
${ }^{1}$ Although, the stopping rule behaviour may not affect sex ratio at birth, but helps in
visualizing the extent of son preference in society through SRLB visualizing the extent of son preference in society through SRLB.

2 Sex preference is measured as the difference in preference of sons minus daughters as reported by the women. The positive values are considered as son preference, while negative is considered as daughter preference, and zero is no preference.
